Introduction •0000	Optimal liquidation	Latency 00000	Dynamic programming 0000	Backtesting on TAQ data	Conclusions O
Optima	al Liquidatio	n			

How to liquidate X shares of an asset?

- 1 Macroscopic time scale:
  - Horizon  $\overline{T} > 0$  over which the shares X need to be liquidated.
  - Depends on *long term* variables: average daily volume, strategic considerations, news events, ...
- 2 Mesoscopic time scale:
  - Trade schedule  $0 \le t_0 \le t_1 \ldots \le t_i \le \ldots \le t_n = \overline{T}$  for the "child" trades.
  - Depends on *medium term* variables: volatility of the stock, risk aversion of the trader, price impact considerations, ...
- **3 Microscopic** time scale:
  - Within a time interval  $(t_i, t_{i+1}]$ , what is the *timing* and the *type of order* used to liquidate the "child" trade?
  - Depends on *short term* variables: limit order book information.

Introduction 00000	Optimal liquidation	Latency 00000	Dynamic programming 0000	Backtesting on TAQ data	Conclusions O
Micros	copic Time	Scale			

- We assume that the trade schedule is **given**.
  - The goal is then to liquidate one lot (the shares x<sub>t</sub>) in the time window (t<sub>i</sub>, t<sub>i+1</sub>], i.e., what is the optimal time τ in [0, T] to sell the lot, where T = t<sub>i+1</sub> t<sub>i</sub> > 0.
  - *T* is typically short, e.g., 1 minute.
  - For such short time periods, observing the limit order book can be very advantageous in identifying good liquidation times.
  - However, **latency** in the trade execution can diminish this advantage!

Introduction 00000	Optimal liquidation	Latency 00000	Dynamic programming 0000	Backtesting on TAQ data	Conclusions O
Latency	/				

- Latency arises in every trade execution:
  - Time of datafeed to travel from exchange to execution machine;
  - 2 The algorithm making a decision;
  - 3 The order being sent back to the market.
- Latency has no effect on deterministic trade schedules.
- In our model the algorithm will take into account that if a market order is sent at time t it will actually be executed at the best price available at time t + I, for latency I > 0.
- This worsen the performance of our optimal liquidation algorithm, thus allowing us to quantify the cost of latency.

### The Imbalance Process

The imbalance process:

$$I(t) = \frac{B(t)}{A(t) + B(t)}$$

B(t) is the bid size, A(t) is the ask size.

- We assume I(t) is a Markov process.
- Imbalance is a predictor of short term price moves
  - As a consequence of a zero-intelligence model: Cont, Stoikov and Talreja (2010)
  - Empirically: Avellaneda, Reed and Stoikov (2011)

00000	000000	00000	0000		O
Motiva	tion				

There is empirical evidence that selling on small imbalances can be profitable:

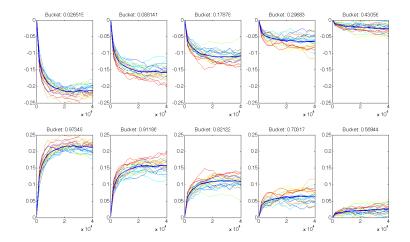

• On each quote *i*, record the imbalance  $I_i$  and the mid price  $S_i^m$ 

▲ロト ▲帰ト ▲ヨト ▲ヨト 三日 - の々ぐ

- At a later quote in the future j, record the mid price  $S_i^m$
- Take averages of  $(S_i^m S_i^m)$  for  $I_i$  in different buckets

## The Optimal Liquidation Problem

• Goal: Identify an optimal time  $\tau$  in [0, T] to sell the share, i.e.,

$$V(t,x) = \inf_{t \le \tau \le T} E[I_{\tau}|I_t = x],$$

for  $x \in [0, 1]$  and  $t \in [0, T]$ , and  $\tau \in T$ , where T is the set of stopping times with respect to  $\sigma(I(t))_{t \ge 0}$ .

In general we may solve

$$V(t,x) = \inf_{t \leq \tau \leq T} E[g(I_{\tau})|I_t = x],$$

# Optimal Liquidation based on Minimizing Imbalance

Define

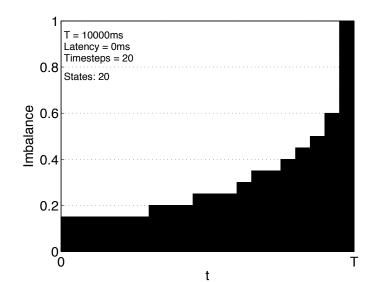

$$D = \{(t, x) \in [0, T] \times [0, 1) : V(t, x) = x\},\$$
  
$$C = \{(t, x) \in [0, T] \times [0, 1) : V(t, x) < x\}.$$

#### Proposition

There exists a non-decreasing function  $w^* : [0, T] \rightarrow [0, 1]$  with  $w^*(T) = 1$ , such that  $D = \{(x, t) \in [0, 1) \times [0, T] : x \le w^*(t)\}$ .

Trading	g with Later	ιсу			

- A trade triggered at time t is executed at time t + L for L > 0.
- Consider

$$V^{L}(t,x) = \inf_{t \leq \tau^{L} \leq T-L} \mathbb{E}[I(\tau^{L}+L)|I(t)=x],$$

where  $\tau^{L} \in \mathcal{T}$ .

• This is equivalent to:

$$V^{L}(t,x) = \inf_{t \leq \tau^{L} \leq T-L} \mathbb{E}[G^{L}(I(\tau^{L}))|I(t) = x].$$

# Trade/No-Trade Regions with Latency

The "trade region" is still connected, but the "no-trade" region does not need to be connected anymore:

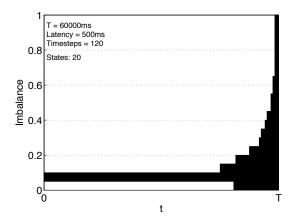

#### Proposition

There exists a non-decreasing function  $w_I^* : [0, T] \rightarrow [0, 1]$  and a non-increasing function  $v_l^* : [0, T] \to [0, 1]$ , with  $v_l^* \leq w_l^*$ ,  $w_t^*(t) = 1$  for  $t \in [T - L, T]$  and  $v_t^* = 0$  for  $t \in [T - L, T]$ , such that

$$D^{L} = \{(t, u) \in [0, T] \times [0, 1) : v_{L}^{*}(t) \le u \le w_{L}^{*}(t)\}.$$

<b>D</b> .					

Discretization Approximation

- Knowing  $V^{L}(t, x)$ , is enough to identify good liquidation times.
- Let  $N, E \in \mathbb{N}$ . Define,

$$k: [0, T] \to K = \{0, \dots, N\}$$
  

$$t \mapsto k(t) = \sup \{n \in \{0, \dots, N\} | nT/N \le t\},$$
  

$$h: [0, 1) \to H = \{1, \dots, E\}$$
  

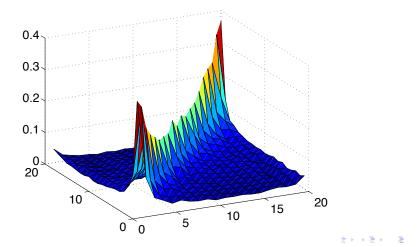

$$x \mapsto h(x) = \lfloor Ex \rfloor + 1.$$

These mappings transform the original state space
 [0, T] × [0, 1) into a *discrete state space* with (N + 1)E states.

Overvie	W.				

Backtesting on TAQ data for 5-years US treasury bonds for 21 days (July 2010).

- The time-weighted average price (TWAP) strategy liquidates one share per minute **independently** of the state of the limit order book.
- Our imbalance-based algorithm will have T equal to 1 minute. For each day we backtest,
  - we compute the optimal execution region, using the empirical transition matrix from the previous day's data
  - we walk through each quote, decide whether we are in the trade region or not
  - if we are in the trade region submit a sell order which will be executed at the bid *L* milliseconds later

Introduction	Optimal liquidation	Latency	Dynamic programming	Backtesting on TAQ data	Conclusions
00000	0000000	00000	0000	00000	0

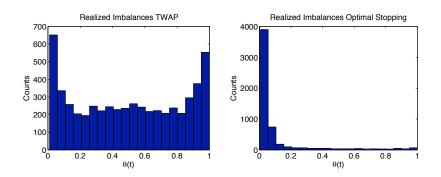

# Optimal Stopping vs. TWAP Strategy

- Consider residuals  $\hat{R} = S_{\tau}^{b} S_{T}^{b}$ , where  $\tau$  is the stopping time from the optimal stopping problem V(t, x).
- Compare 5,649 intervals of length 1 minute.
- Without latency the optimal liquidation strategy saves on average 31 \$ per share, i.e., **1/3 of the spread** (Spread is 78\$ for 5 yrs US-treasury bonds):

$$\begin{array}{c|c} & \mathbb{E}[\hat{R}] & \sigma(\hat{R}) \\ \hline \\ \text{Optimal policy vs. TWAP} & 31.26 \$ & 49.14 \$ \\ \end{array}$$

Cost of	Latency				

• Cost of latency:

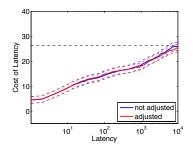

$$COL = \mathbb{E}[S_b(\tau) - S_b(\tau + L)],$$

where  $\tau$  is the stopping time induced by V(t, x).

• Note, we calculate the COL with respect to the **optimal strategy with no latency**.

Introduction	Optimal liquidation	Latency	Dynamic programming	Backtesting on TAQ data	Conclusions
00000	0000000	00000	0000	000000	0

## The Cost of Latency cont.

- 10ms latency  $\approx$  10\$ per share.
- For latencies ≥ 2000ms (i.e., 2 secs) the advantage of observing the limit order book diminishes (performance becomes similar to TWAP).
- Adjusting the liquidation policy brings only minor improvement in the performance.

Introduction 00000	Optimal liquidation	Latency 00000	Dynamic programming 0000	Backtesting on TAQ data	Conclusions •
Conclus	sions				

- We consider an optimal stopping problem that depends on:
  - Information found in the order book;
  - Latency;
  - The time left to catch up with the TWAP algorithm.
- The solution comes in the form of a trade/ no-trade regions in the imbalance process.
- We estimate model parameters with level-I trades and quotes data.
- We find that our optimal liquidation algorithm significantly outperforms a TWAP algorithm.
- We quantify the cost of latency.
- Reference: Optimal Asset Liquidation Using Limit Order Book Information
